

WEIGHING THE DARK MATTER HALO

JACOB L. BOURJAILY*

*Michigan Center for Theoretical Physics,
University of Michigan, Ann Arbor, MI 48109-1120*

The dark matter problem will be solved only when all of the dark matter is accounted for. Although wimps may be discovered in direct detection experiments soon, we will not know what fraction of the dark matter halo they compose until we measure their local density. In this talk, I will offer a novel method to determine the mass of a wimp from direct detection experiments alone using kinematical consistency constraints. I will then describe a general method to estimate the local density of wimps using both dark matter detection and hadron collider data when it becomes available. These results were obtained in collaboration with Gordon Kane at the University of Michigan.

1. Introduction

The direct detection of wimps in the galactic halo would be an enormous triumph of experimental and theoretical particle cosmology, have deep implications for our understanding of the universe, and would explain (at least) some of the dark matter in the universe. However, it is unreasonable to assume that the entire dark matter halo is composed of only the wimp observed.

What fraction of the dark matter halo is represented by a particular wimp is a question that cannot be answered by direct detection experiments alone or colliders alone. Even if a stable, weakly interacting massive particle is discovered at the LHC, no amount of collider data can measure its *actual* local density. Alternatively, even if many direct detection experiments unambiguously observe the scattering of wimps from the halo, these experiments cannot identify the wimp or determine its couplings—crucial to measuring the local density. This point was first raised technically in Ref.¹. In this talk, I will present a general way to address the cosmological significance of wimps observed in direct detection experiments using data and bounds from colliders. For a more detailed discussion, see Ref.².

2. The No-Lose Theorem vs. Our Ability to Win

Let us imagine that a weakly interacting massive particle χ has been unambiguously observed in direct detection experiments. There is no reason to suspect that χ is *all* the dark matter. In fact, it is very easy to find models where detectable wimps compose only a fraction of a percent of all the dark matter. Using the framework of the DarkSUSY code³, we randomly generated some six thousand constrained MSSMs and found that for any signal rate, the relic density fluctuates over at least two orders of magnitude^{2a}. It appears as if the detection signal rate and relic density are largely uncorrelated: a wimp with a low relic density may be just as observable as one making up most of the dark matter.

The fact that particles with even small relic densities can have large detection signals has been noted by many authors (see, *e.g.* Ref.⁴) and has sometimes referred to as the ‘no-lose theorem:’ experimentalists may not lose out on discovering even a very tiny faction of the dark matter halo. However, the no-lose theorem also implies that a wimp discovery could easily represent a negligible fraction of the dark matter. Therefore, although wimps may be discovered in the near future, the dark matter problem will not be solved until the density of wimps has been directly determined, and all the dark matter is accounted for.

3. Dark Matter Direct Detection Rates

In general, the wimp-nucleon elastic scattering rate is a function of the cross section for scattering, nuclear physics describing the detector, and the local velocity profile of the wimp fraction of the dark matter halo. If a detector is composed of nuclei labeled by the index j , each with mass fraction c_j , then the differential rate of wimp scattering at recoil energy q is given by^b,

$$\left. \frac{dR}{dQ} \right|_{Q=q} = \frac{2\rho_\chi}{\pi m_\chi} \sum_j c_j \int_{v_{\min,j}(q)}^{\infty} \frac{f(v,t)}{v} dv \left\{ F_j^2(q) [Z_j f_p + (A_j - Z_j) f_n]^2 + \frac{4\pi}{(2J_j + 1)} [a_0^2 S_{j00}(q) + a_1^2 S_{j11}(q) + a_0 a_1 S_{j01}(q)] \right\}, \quad (1)$$

^aOnly an upper bound on the relic density, consistent with WMAP, was imposed while generating these models.

^bA detailed discussion of equation 1 can be found in most modern reviews of dark matter, (see, *e.g.*, Ref.⁵).

Figure 1. The function $\zeta(m'_\chi)$ where the wimp corresponds to the neutralino in the MSSM specified by ATLAS SUSY point 2. The models and data were generated within the framework of the DarkSUSY package.

where $f(v, t)$ is the halo velocity profile, $F_j^2(q)$ and $S_{j_{mn}}(q)$ are nuclear form factors, $a_0 \equiv a_p + a_n$ and $a_1 \equiv a_p - a_n$, and the constant parameters $f_{p,n}$ and $a_{p,n}$ describe the coherent and incoherent wimp-nucleon scattering cross sections, respectively.

From the equation above, it is clear that to determine the density ρ_χ , one must identify the particle, determine its mass, estimate the halo profile, and ‘know’ the interaction parameters from the theory describing χ . Each of these require enormous efforts of both dark matter and collider experiments.

4. Determining the Wimp Mass

Initially, perhaps the most important parameter of χ to determine is its mass. Not only does m_χ determine the particle’s kinematics, but it may be critical to the identification of the particle^c.

There are two known ways to determine m_χ from direct detection data alone. One method, using the annual modulation crossing energy, was described in a dark matter review article by Primack *et. al.* in 1988^{6d}. The other method has been developed by the author and is described presently.

If the halo velocity profile and m_χ are known, then direct detection data from different detector materials and different energies can be used to

^cOne may hope that accelerators observe a weakly interacting, stable, massive particle with the same mass as χ .

^dAlthough it seems unlikely to have originated in a review article, we have been unable to find any earlier reference.

solve for $\sqrt{\rho_\chi}f_{p,n}$ and $\sqrt{\rho_\chi}a_{p,n}$ by inverting equation 1. If the halo velocity profile can be approximated, only m_χ is required to compute $\sqrt{\rho_\chi}f_{p,n}$ and $\sqrt{\rho_\chi}a_{p,n}$ with sufficient data. We can generally expect to have many more measurements than the minimum required to solve the system of equations once wimps are observed.

Because the interaction parameters are constant, all linearly independent combinations of measurements used to solve for the scaled interaction parameters must agree, if the correct mass were used in the derivation. This motivates us to define a ‘kinematical consistency’ function $\zeta(m'_\chi)$,

$$\zeta(m'_\chi) \equiv \sqrt{\rho_\chi} \sum_{i \neq j} \left\{ (a_p(i) - a_p(j))^2 + (a_n(i) - a_n(j))^2 + \text{similar terms} \right\},$$

which compares the values of $\sqrt{\rho_\chi}f_{p,n}$ or $\sqrt{\rho_\chi}a_{p,n}$ obtained using different independent subsets of the data—indexed by i, j —as a function of m'_χ used to invert the equations. It is obviously necessary that $\zeta(m'_\chi) = 0$ when $m'_\chi = m_\chi$ ^e.

To determine the wimp mass, one varies m'_χ until $\zeta(m'_\chi) = 0$. We applied this test to some six thousand random, constrained MSSMs. For every single model tested, the correct mass was determined to near-arbitrary precision. Figure 1 illustrates a typical plot of $\zeta(m'_\chi)$. Notice that it has an extremely sharp minimum within a few GeV of the true wimp mass. It should be noted, however, that experimental uncertainties and resolutions were not considered during these calculations.

5. Neutralino Dark Matter and a Strict Lower Bound on ρ_χ

Before we can compute ρ_χ , the interaction parameters $f_{p,n}$ or $a_{p,n}$ must be ‘known.’ These interaction parameters depend on very detailed knowledge of the particle physics of χ . Let us consider the specific case in which the discovered particle is the neutralino. The interaction parameters will then depend on many details of the MSSM—these may not be known until well after dark matter particles have been discovered. Nevertheless, even with extremely limited knowledge of the MSSM, we can estimate the parameters using partial data, bounds, and constraints.

For example, we have found that given bounds on $\tan\beta$ and a lower bound on the lightest squark mass, $m_{\tilde{q}}$, there is a strict upper bound for the incoherent χ -quark scattering parameters. In this case, it can be shown,

^eThis may not be a sufficient condition, however; although, we have found no example where $\zeta(m'_\chi) = 0$ when $m'_\chi \neq m_\chi$.

that the magnitude of a_u is strictly bounded by

$$a_u \leq -\frac{g^2}{16m_W^2}(N_{\tilde{H}_1}^2 - N_{\tilde{H}_2}^2) + \frac{g^2}{8} \frac{1}{(m_{\tilde{q}_\ell}^2 - (m_\chi^2 + m_u)^2)} \left\{ \frac{17}{18} \tan^2 \theta_W N_{\tilde{B}}^2 + \frac{1}{2} N_{\tilde{W}}^2 \right. \\ + \frac{m_u^2}{m_W^2 \sin^2 \beta_\ell} N_{\tilde{H}_2}^2 + \frac{1}{3} \tan \theta_W |N_{\tilde{B}}| |N_{\tilde{W}}| \cos(\alpha_{\tilde{W}}) \\ \left. + \frac{m_u}{m_W \sin \beta_\ell} |N_{\tilde{W}}| |N_{\tilde{H}_2}| \cos(\alpha_{\tilde{H}_2} - \alpha_{\tilde{W}}) - \frac{m_u}{m_W \sin \beta_\ell} \tan \theta_W |N_{\tilde{B}}| |N_{\tilde{H}_2}| \cos(\alpha_{\tilde{H}_2}) \right\},$$

where $\alpha_{\tilde{H}_2}$, and $\alpha_{\tilde{W}}$ are the relative phases between $N_{\tilde{H}_2}$, $N_{\tilde{W}}$ and $N_{\tilde{B}}$, respectively. This expression has six real unknowns. Notice that by the normalization of the neutralino wave function, the parameter space is compact. Therefore, a_u can be *absolutely* maximized with respect to all six unknowns. It should be emphasized that this analysis is for the most general softly-broken MSSM; no *ad hoc* supersymmetry breaking scenarios—such as mSUGRA—were assumed.

Because we can determine $\sqrt{\rho_\chi} a_{p,n}$, the strong upper bounds on $a_{p,n}$ directly translate into strong lower bounds on ρ_χ . To test this idea, we considered some six thousand randomly generated, constrained MSSMs. For each of these models, upper bounds were calculated for $a_{p,n}$ assuming 10% uncertainty in $\tan \beta$ and a lower bound on the lowest squark mass of either 200 GeV or the actual mass of the lightest squark, whichever is less. The specific gauge content of the neutralino was taken to be known for each model for computational simplicity^f. Using the upper bounds for $a_{p,n}$, we obtain a lower bound on the local density ρ_χ .

Figure 2 illustrates the results of using this algorithm. Notice that the estimated local density is always strictly less than the true local density. Also, for many models the lower bound is not such a poor estimate.

6. Conclusions

We have seen that, by itself, a discovery of dark matter particles in our galactic halo cannot solve the dark matter problem. However, combined with data from colliders to identify a particle and determine its interaction parameters, we can generally estimate its local density.

We presented a robust, model independent method to determine the mass of a wimp using direct detector data alone. We have shown explicitly

^fIf the gauge content of the neutralino was unknown, the interaction parameters could have been maximized with respect to these parameters as described earlier. In general, therefore, the upper bounds plotted are more restrictive than they would be in practice.

Figure 2. This plot compares the lower bound and estimate of the local density computed using the strong upper bound for $a_{p,n}$ to the true local density for each model.

how one can determine or estimate ρ_χ in the case where χ is the neutralino.

Although the dark matter problem may not be solved immediately when wimps are discovered, there are clear and general ways to address their cosmological significance.

Acknowledgements

This research was done in collaboration with Gordon Kane of the University of Michigan and was supported by the Michigan Center for Theoretical Physics and the National Science Foundation's 2004 REU program.

I would like to thank the organizers of the 5th International Workshop on the Identification of Dark Matter for the wonderful program.
